Trust: the new model

The Distributed Ledger

Intuition:

If everyone has a copy of the **ledger** (the book where transactions get registered), it is always possible to verify that **what is promised by one party is true**, without the need for external intermediaries

Trust: distributed ledger

If...

- All participants keep track of each other's current balance
- Each operation is registered by every member of the system
- No operation can be authorized without first being accepted and registered by the other participants

Trust: distributed ledger

Then...

- **Bob can always be sure that Alice has \$ 20**
- **Alice can not spend the same money twice (*double spending*)**

Systems based on blockchain, such as **Bitcoin** (that we use in the following as a notable seminal example), successfully implement a distributed ledger that can provide those guarantees

Bitcoin: a first glossary

- **Address:** an alphanumeric string that represents an identity on the ledger, used as a reference for sending currencies; each identity is associated with a **pair of keys** (one private and one public) which allows transactions to be carried out with one's own cryptocurrency
- **Transaction:** represents the sending of cryptocurrency **from one address to another** (may involve more than one address)
- **Block:** the basic entity of the blockchain, which contains a set of valid, immutable and irreversible transactions

Bitcoin: a first glossary (**cont'ed...**)

- **Network:** is a peer-to-peer network, in which each participant in the network is both a client and a server (generically called **node**)
- **Miner:** node belonging to the network that generates new bitcoins and records new transactions (to do this it must solve the so-called **Proof of Work**, thus acquiring the right to insert **a new block** to the network, as detailed below)
- **Wallet:** node belonging to the network that maintains identities

Bitcoin: node functionalities

Bitcoin nodes can implement four main functionalities:

- **Wallet:** nodes able to store identities
- **Miner:** nodes able to execute the mining operation
- **Full Blockchain:** nodes that store the whole ledger state
- **Network:** nodes that spread **new blocks** and **transactions** received **over the network**

Bitcoin: node roles

Bitcoin: mining and transactions

- When a user wishes to send BTCs to another user, she generates a new **transaction** using **her address** and publishes it, **protecting it with an asymmetric key mechanism**, sending it to the miners she knows that propagate it to the whole network (in addition to the desired amount, a commission fee must be added)
- Miners **collect transactions**, while seeking a value that satisfy the *Proof-of-Work* challenge
 - **The first miner that succeeds in this intent, creates and publishes a new block**
 - The other miners validate the block (verifies the puzzle and the hash pointer) and add the block to their ledger
 - Transactions are **immutably** added to the block, they are an integral part of it and can no longer be changed
 - The miner **earns the reward** for the operation (currently \$12.5), as well as the **commissions** included in the mined transactions

Miners create new blocks and add pending transactions to the chain

Bitcoin: *Proof-of-Work*

The search for the value of **nonce** is the Bitcoin *Proof-of-Work* challenge that the miners must win:

$$H(\textit{nonce} \parallel \textit{prev_hash} \parallel \textit{tx} \parallel \textit{tx} \parallel \dots \parallel \textit{tx}) < \textit{target}$$

- After adding the transactions it has received, the miner searches for a **nonce** value such that **the hash of the whole block is less than a given value (target)**; this operation requires a lot of resources and luck
- The **level of difficulty** is chosen each 2016 blocks (about 2 weeks) through an algorithm known to all, to **maintain the average rhythm of a new block generation every 10 minutes**

SHA-2

Diagram illustrating the SHA-2 processing flow. The input is a block of 8 bytes (A-H). These bytes are processed by four parallel computation blocks: Ch, Σ1, Ma, and Σ0. The outputs of these blocks are combined to produce a new 8-byte block (A-H). The diagram also shows a feedback loop from the output of the Σ0 block back to the input of the Ch block, and a feedback loop from the output of the Σ1 block back to the input of the Σ0 block. The final output is a new 8-byte block (A-H).

ECDSA

Diagram illustrating the ECDSA process. It shows a red elliptical curve on a 2D coordinate system. Two points, P1 and P2, are marked on the curve. A dashed line connects them, and a vertical dashed line is drawn from P2 down to the x-axis. The point P3 = P1 + P2 is marked on the curve, and a vertical dashed line is drawn from P3 down to the x-axis. The equation $P3 = P1 + P2$ is written below the curve.

SHA-2

The diagram illustrates the SHA-2 architecture. It features an input register with blocks A through H. These blocks are connected to a series of processing blocks: Ch, Σ1, Ma, and Σ0. The output of the Ch and Σ1 blocks is combined with the input of the Ma and Σ0 blocks to produce the final output blocks A through H. The diagram also shows the input of the Ch and Σ1 blocks being combined with the input of the Ma and Σ0 blocks to produce the final output blocks A through H. The input of the Ch and Σ1 blocks is also combined with the input of the Ma and Σ0 blocks to produce the final output blocks A through H.

ECDSA

The diagram shows a 2D coordinate system with a red elliptic curve. Two points, P1 and P2, are marked on the curve in the upper-left quadrant. A dashed line connects them, and a vertical dashed line is dropped from the intersection of this line with the curve to the lower-right quadrant, where the point P3 is marked. The equation $P3 = P1 + P2$ is written below the curve.

Hash crittografico: problemi e strumenti

- .trovare $x, y : H(x) = H(y)$
- .dato h , trovare $x : H(x) = h$
- .dato y , trovare $x : H(x) = H(y)$

Hash pointer (simbolo $H(\uparrow)$): chiave primaria per accedere a dati e controllarne l'integrità

Efficienza: blocchi contenenti più documenti

Given n items, how much does it cost to prove membership of an item in a hash pointer structure?

$O(n)$

$H(\quad)$

Bitcoin: blocco di transazioni

Proving Membership in a Merkle tree

Given n items, how much does it cost to prove membership?

$O(\log(n))$

Proving Membership in a Merkle tree

Struttura di un Blocco

Field name	Type (Size)	Description
nVersion	int (4 bytes)	Block format version (currently 2).
HashPrevBlock	uint256 (32 bytes)	Hash of previous block header $SHA256^2(nVersion \dots nNonce)$.
HashMerkleRoot	uint256 (32 bytes)	Top hash of the Merkle tree built from all transactions.
nTime	unsigned int (4 bytes)	Timestamp in UNIX-format of approximate block creation time.
nBits	unsigned int (4 bytes)	Target T for the proof of work problem in compact format. Full target value is derived as: $T = 0xh_2h_3h_4h_5h_6h_7 * 2^{8*(0xh_0h_1-3)}$
nNonce	unsigned int (4 bytes)	Nonce allowing variations for solving the proof of work problem.
#vtx	VarInt (1-9 bytes)	Number of transaction entries in <i>vtx</i> .
vtx[]	Transaction (Variable)	Vector of transactions.
